Abstract

β -amyloid ($A\beta_{1-42}$) is produced by proteolytic cleavage of the transmembrane type-1 protein, amyloid precursor protein. Under pathological conditions, $A\beta_{1-42}$ self-aggregates into oligomers, which cause synaptic dysfunction and neuronal loss, and are considered the culprit of Alzheimer's disease (AD). However, $A\beta_{1-42}$ is mainly monomeric at physiological concentrations, and the precise role of monomeric $A\beta_{1-42}$ in neuronal function is largely unknown. We report that the monomer of $A\beta_{1-42}$ activates type-1 insulin-like growth factor receptors and enhances glucose uptake in neurons and peripheral cells by promoting the translocation of the Glut3 glucose transporter from the cytosol to the plasma membrane. In neurons, activity-dependent glucose uptake was blunted after blocking endogenous $A\beta$ production, and re-established in the presence of cerebrospinal fluid $A\beta$. APP-null neurons failed to enhance depolarization-stimulated glucose uptake unless exogenous monomeric $A\beta_{1-42}$ was added. These data suggest that $A\beta_{1-42}$ monomers were critical for maintaining neuronal glucose homeostasis. Accordingly, exogenous $A\beta_{1-42}$ monomers were able to rescue the low levels of glucose consumption observed in brain slices from AD mutant mice.

Keywords

Alzheimer's disease, β -Amyloid, Glucose, IGF-IR, Glut3

Introduction

Sporadic age-related form of AD is the most frequent yet incurable type of dementia. Difficulties in advancing disease understanding and clinical interventions partly depend on complex interactions between disease determinants, namely the toxic β -amyloid₁₋₄₂ ($A\beta_{1-42}$) species [1], and age-related risk factors, including the decline of insulin-like growth factor 1 (IGF-1) functions [2], and the occurrence of peripheral insulin resistance or diabetes [3]. These intervening factors, among others, might progressively overcome the ability of the brain cognitive reserve to buffer the impact of the pathology on cognitive functions. Specifically, Stranahm and Mattson have hypothesized that the cognitive reserve relies on insulin/neurotrophic factor signaling and glucose metabolism that all set the brain metabolic efficiency [4]. The AD brain shows impairments of insulin/IGF-1 signaling [5] and glucose metabolism [6], which only in some cases depend on a comorbid systemic disease [5], and are largely unexplained. Talbot and colleagues [7] have provided direct evidence that AD brain tissue is insulin resistant in the absence of diabetes, and that histological biomarkers of insulin resistance co-localize with $A\beta$ plaques. Interestingly, in the same study, they found a strong resistance of type-I IGF receptor (IGF-IR) to ligand activation even in brain regions where amyloid plaques are found in a very late stage of AD [7]. It remains unknown whether and how this last finding is relevant to the pathophysiology of AD and is related to the low rate of brain glucose metabolism that starts decades before the clinical onset of dementia [6,8,9]. Here we provide evidence that, both in native and recombinant systems, IGF-IRs can be activated by the monomer of $A\beta_{1-42}$, the predominant form of the protein at physiological concentrations [10]. In recombinant cells, monomeric $A\beta_{1-42}$ acts as a positive allosteric modulator of IGF-IRs endowed with a small intrinsic efficacy, thereby enhancing IGF-1 effects. Through IGF-IR activation, $A\beta_{1-42}$ monomers control glucose uptake in neurons under both basal and depolarizing conditions. Interestingly, $A\beta_{1-42}$ monomers rescue the low levels of glucose consumption observed in brain slices from AD transgenic mice, which are resistant to IGF-1 stimulation. We suggest that a defective IGF-

IR signaling contributes to AD progression *via* a disease-specific mechanism involving the loss of receptor activation by A β monomers, which become depleted when pathological aggregates are formed.

Materials and Methods

Synthesis of Pentapeptides

Pentapeptides (KLVFF, VFLKF, klvff, ffvlk) were synthesized by means of microwave-assisted solid phase peptide synthesis on a CEM “Liberty” peptide synthesizer using standard 9-fluorenylmethoxycarbonyl (Fmoc) chemistry. Peptides were cleaved off from the solid support using a mixture of Trifluoroacetic acid (TFA)/water (H₂O)/tri-isopropyl-silane (TIS) 95/2.5/2.5 (v/v/v), then precipitated with cold freshly distilled diethyl ether. Crude peptides were purified by preparative RP-HPLC. Samples identity was confirmed by ESI-MS (Calculated mass for C₃₇H₅₅N₇O₆: 693.42; Observed [M+H]⁺: 694.58).

To control for KLVFF effects, in addition to the retroinverse ffvlk, which maintains the overall spatial topology of KLVFF, we chose to synthesize both the scrambled peptide, VFLKF, and the D-enantiomer klvff. The latter is very likely to bind A β ₁₋₄₂ as the parent KLVFF [11], thus ruling out the possibility that KLVFF acts by stabilizing endogenous A β monomers.

Peptide Sample Preparation

A β ₁₋₄₂ and A β ₁₋₁₆ were purchased from Bachem Distribution Services GmbH, Germany. A β ₁₇₋₄₂ was purchased from Innovative Peptide Solutions, Germany. All peptides were dissolved in trifluoroacetic acid (TFA) at a concentration of 1mg/ml and sonicated for 10 min. TFA was removed by gentle streaming of argon. Peptides were then dissolved in 1,1,1,3,3,3-hexa-fluoro-2-propanol (HFIP) and incubated at 37°C for 1 h. Following argon streaming, peptides were dissolved again in HFIP, lyophilized and then resuspended in 5 mM anhydrous dimethyl sulfoxide (DMSO) prior to dilution to 100 μ M in ice-cold cell culture medium DMEM-F12.

Circular Dichroism Measurements

CD spectra were recorded at 37°C under a constant nitrogen flow on a JASCO model J-810 spectropolarimeter, equipped with a Peltier thermostatted cell holder. CD spectra were run in the far-UV region (200-260 nm) using 1 cm path length cuvettes. CD spectra were acquired every 30 min over a time course of 1200 min. Buffer contribution to the CD intensity was subtracted from peptide CD spectra.

Thioflavin T (ThT) Fluorescence Measurements

Fluorescence measurements were performed on a Perkin Elmer LS 55 spectrophotofluorimeter equipped with a thermostatic cell holder. The experiments were carried out at 37°C using a 1 cm light path quartz. ThT (45 μM) emission fluorescence was followed for 1200 min by monitoring the increase in the dye intensity at 480 nm, with a 440 nm excitation wavelength. The excitation and emission slit widths were set at 5 nm.

Rayleigh Scattering Measurements

Rayleigh scattering measurements were performed on a Perkin Elmer LS 55 spectrophotofluorimeter at 37°C in a 1 cm path-length cell. Peptide samples were excited at 400 nm and scattering was monitored for 1200 min at 400 nm. Both excitation and emission slits were fixed at 5 nm.

IGF-IR and IR Phosphorylation Assay

Clones of R⁻ cells (3T3-like mouse fibroblasts with a disrupted IGF-IR gene), stably transfected with either the human IGF-IR (R⁺) or the human IR-A cDNA (R⁻ IR-A), were obtained as previously described [12]. Cell lysates from R⁻IR-A cells or R⁺ cells (40 μg protein/well) were immunocaptured in Maxisorp Break-Apart immunoplates (Nunc) coated with antibodies MA-20 (Novus Biologicals), which recognizes the IR α-subunit, and αIR-3 (Calbiochem), which recognizes the IGF-IR α-subunit, at a concentration of 2 μg/ml and 1 μg/ml, respectively, in 50 mM sodium bicarbonate (pH 9.0) overnight at 4°C. After washing,

the immunocaptured receptors were incubated with increasing concentrations of either porcine insulin (Sigma-Aldrich) or recombinant human IGF-I (PeproTech) (in 50 mM HEPES-buffered saline (pH 7.6), 150 mM NaCl, 0.1% TritonX 100, BSA 0.05%, containing 10 μ M ATP, 10 mM MgCl₂ and 2 mM MnCl₂) in the presence or absence of mAb₁₋₄₂. After 2 h at RT, the plates were washed and the captured phosphorylated proteins were incubated with biotin-conjugated anti-phosphotyrosine antibody 4G10 (0.3 μ g/ml in 50 mM HEPES (pH 7.6), 150 mM NaCl, 0.05% Tween 20, 1% BSA, 2 mM sodium orthovanadate, 1 mg/ml bacitracin) for 2 h at RT and then with peroxidase-conjugated streptavidin. The peroxidase activity was determined colorimetrically by using the TMB microwell peroxidase substrate system (KPL). The reaction was stopped by the addition of 1.0 M H₃PO₄, and the absorbance was measured at 450 nm.

Neuronal Cultures: Preparation and Treatments

Animal care and experimentation was in accordance with institutional guidelines. Cultures of pure cortical neurons were obtained from rats at embryonic day 15 as described previously [13]. Cultures of mixed cortical cells, containing both neurons and glia, were obtained from rats at embryonic day 17 and grown onto poly-D-lysine coated 16 mm multiwell vessels (4x10⁵ cells/well) as described previously [13]. Mature cultures, at 14-16 days *in vitro* (DIV), were used for the study. All experiments were performed always after extensive washing of the cultures to avoid any interference with serum IGF-1/IGFBP3/ALS ternary complexes.

Mature pure neuronal cultures at 7 DIV were deprived from insulin and, where required, peptide monomers were added and maintained for 48 h. AG1024 (100 nM) and PPP (500 nM) were applied for 30 min before insulin deprivation. Neuronal survival was assessed by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) reduction assay.

Mixed cortical cultures at maturation were exposed to 300 μ M NMDA for 10 min at room temperature in a HEPES-buffered

salt solution. Neuronal toxicity was examined 24 h later by light microscopy and quantified after staining with trypan blue (0.4% for 5 min). Stained neurons were counted from three-random fields/well. Peptide monomers were added in combination with NMDA. Where required, AG1024 (100 nM) and PPP (500 nM) were applied 15 min before the excitotoxic pulse.

IGF1-release in neuronal cultures was assessed by the IGFBP-blocked IGF-I ELISA (ALPCO Diagnostics). Cultures were exposed to the washing protocol utilized for all the experiments and IGF-1 content was quantitated in the culture buffer within 2 h. Low levels of IGF-1 were generally found under these conditions (about 0.003 nM). However, IGF-1 levels strictly depended on the experimental condition. For example, a brief NMDA pulse lead to a 5 fold increase in the release (up to 0.017 nM). Since the assay detected total IGF-1 (free and IGFBP-bound), measurements could not provide indications about the active quote of the factor.

Cultures of APP-null neurons were obtained as in Giuffrida et al. [13] except that cortices from newborn mice (within 12 hours from birth) were used. Homozygous APP-null male and female mice (B6.129S7-APPTM1DBO/J) on a C57BL/6J genetic background were purchased from Charles River, and the colony has been established in the animal house of the University of Catania.

Imaging of 6-NBDG up-take in Neurons by Laser Scanning Confocal Microscopy (LSM)

Neurons were plated on glass bottom culture dishes and were used at 6-8 DIV. For the experiments, cultures were rinsed with glucose-free HCSS (120mmol/l NaCl, 5.4 mmol/l KCl, 1.8mmol/l CaCl₂, 20mmol/l HEPES pH 7.4) and kept for 45 min under glucose deprivation followed by exposure for 30 min to either mAb₁₋₄₂ (100 nM), or recombinant rat IGF-1 (5ng/ml, R&D Systems). The non-hydrolyzable glucose analog 6-NBDG was allowed to be internalized into neuronal cells at 37°C and 5% CO₂ for 10 min. 6-NBDG⁺ neurons were imaged by using an

Olympus FV1000 LSM. Images were captured at 488 excitation/505-550 emission.

Assessment of 6-NBDG uptake in Neurons by Cytofluorimetric Analysis

Neurons were grown onto 35 mm dishes and the experiments were performed at 7 DIV. Cultures were rinsed in glucose-free HCSS and maintained for 45 min under glucose deprivation followed by exposure to either $m\text{A}\beta_{1-42}$ (100 nM) or IGF-1 (5ng/ml) for 30 min, or to KCl (40 mM) for 15 min. PPP (500nM) was added 15 min before $m\text{A}\beta_{1-42}$. When required, a γ -secretase inhibitor (γ -sec-Inhibitor IX, Calbiochem, 100 nM) was added 2h before glucose deprivation and maintained throughout the experiment. 6-NBDG (100 μ M) was added 10 min before ending the experiment by rinsing the cells twice with ice-cold phosphate buffered saline (PBS). Neurons were scraped into ice-cold PBS and maintained at 4°C for the cytofluorimetric analysis (cytomics FC500, Beckman Coulter). 20.000 Events for experimental condition (each in triplicate) were collected.

Assessment of Glucose Uptake in Neurons Exposed to Human CSF

Neurons were grown into 96 well plates and the experiments were performed at 7 DIV. Before the experiment, glucose concentration was measured in all CSF samples by glucose meter, and glucose levels were therefore adjusted to the highest measured value. For the experiment, cultures were rinsed in glucose-free artificial CSF (124 mM NaCl, 2.5 mM KCl, 2 mM MgSO_4 , 1.25 mM KH_2PO_4 , 26 mM NaHCO_3 , 2.5 mM CaCl_2) and maintained for 45 min under glucose deprivation. γ -Sec-inhibitor IX (Calbiochem, 100 nM) was added 2h before glucose deprivation and maintained throughout the experiment. Following deprivation, cultures were shifted into 50 μ l CSF/well and preliminary experiments were carried out to assess neuronal viability. Under this condition, a fast excitotoxic event occurred and thereafter all experiments were carried out in the presence of the NMDA receptor antagonist, MK-801 (1 μ M). Cultures were

maintained in CSF with MK-801 for 40 minutes, during which no glucose uptake occurred.

Parallel experiments carried out in artificial CSF showed that glucose uptake in response to KCl, at the usual concentration of 40 mM, was blunted by the presence of MK-801 (glucose consumption (mg/dl): 52.75 ± 1.5 and 47.27 ± 1.6 - basal vs. KCl, respectively). However, a relevant glucose uptake was observed by rising KCl concentration to 400 mM (glucose consumption (mg/dl): 53.25 ± 2.8 and 38 ± 2.3 - basal vs. KCl, respectively).

Neurons were therefore maintained in CSF + MK-801 for 40 minutes, then glucose consumption was measured in a 5 μ l aliquot by glucose meter before adding 400 mM KCl for 15 min. Measurements of glucose consumption were taken again at the end of the pulse, and glucose uptake was calculated with respect to the initial values.

L6 Cell Cultures

L6 rat skeletal muscle cells (EACC) were cultured in 5% CO₂ in DMEM (Invitrogen) supplemented with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin. Once the cells reached 80% confluence, they were split (using 0.25% trypsin-EDTA) into fractions and propagated or seeded to be used in the experiments. To induce differentiation into the myotubes that were used for experiments, cells were made confluent and the concentration of FBS was then reduced to 1% for 24 – 48 h. Cells were passaged biweekly. Passages 10–30 were used for all the experiments.

Measurement of 6-NBDG Uptake in L6 Cells

L6 myotubes, seeded in 22 mm glass bottom dishes, were placed in Krebs' Ringer buffer (136 mM NaCl, 20 mM HEPES, 2 mM NaHCO₃, 0.5 mM NaH₂PO₄, 3.6 mM KCl, 0.5 mM MgCl₂, and 1.25 mM CaCl₂, pH 7.4) without glucose for 45 min. When required, inhibitors were added for 30 min during the glucose starvation time. The stimulation of glucose uptake was obtained

by incubating cells for 15 more min with either IGF-1, mA β ₁₋₄₂, or KVLFF. Cells were then loaded with 100 μ M 6-NBDG for 15 min. The concentration and incubation time were chosen as the best for giving an adequate signal/noise ratio. After the loading period, culture dishes were washed twice and placed on the stage of a FV1000 LSC microscope. Cultures were excited at 488 nm, and 6-NBDG was imaged at 505–550 nm emission wavelength.

Indirect Glut3 Immunofluorescence Analysis

To mimic the experimental conditions under which glucose uptake was observed, cells seeded in round coverslips (pure cortical neurons or L6 myotubes) were washed repeatedly and glucose starved for 30 min. When required, PPP was added during the glucose starvation time. Cells were then washed again and stimulated for 10 min with monomeric A β ₁₋₄₂ (100 nM), KCl (40 mM), or KLVFF monomers (100 nM) in the presence of glucose. Cells were then fixed in 2% formaldehyde and permeabilized using 0.1% Triton X-100. Unspecific binding was blocked by 30 min of incubation in 4% bovine serum albumin (BSA) in 0.1% Triton X-100-PBS. Glut-3 was detected by incubating over-night cells with rabbit anti-Glut-3 antibody (1:100, Abcam). Counterstaining was obtained by over-night incubation with mouse anti-actin (1:200, Sigma-Aldrich). After PBS washing, cells were exposed for 1 h at RT to the respective secondary antibody (anti-rabbit AlexaFluor 546 or anti-mouse AlexaFluor 680). Coverslips were mounted with the ProLong Gold antifade mounting medium (Invitrogen) and examined under a FV1000 LSC microscope using the Fluoview Olympus image software.

Imaging was carried out using a 63 Plan-Apo/1.4-NA oil-immersion objective. Standard 3 confocal channel (3 photomultiplier detectors) acquisitions were made by using the following lasers, mounted on a laser combiner: Multi-line Argon laser (457nm, 488nm, 515nm), total 30mW HeNe-Green laser (543nm), 1.5mW HeNe-Red laser (633nm), 10mW. Single or multiple optical sections (0.42 μ m z axis) through the middle of the cells were acquired for each field. The pinhole was adjusted

to keep the same size of z-optical sections for all the analysis. Sequential mode imaging was performed to ensure that there was no crosstalk between the channels. Ten random fields for each treatment were imaged, with each treatment repeated twice in three separate experiments. Quantitative analysis was carried out using the FV1000 single particle analysis software (release 2). Glut3 signal spread was calculated as follows: for each microscopic field a z-stack series, made up of 20 slices (0.42 μM thickness each), was acquired. Then, the difference between the average fluorescence intensity/pixel, measured as z-projection in the z-stack series, and the average fluorescence intensity/pixel, measured for a single slice corresponding to the middle of the neuron, was calculated.

Detection of the Glut3 Exofacial Domain

Specific detection of the N-terminal extracellular domain of Glut3 was achieved by indirect immunofluorescence of non-permeabilized neurons, using a goat antibody raised against a peptide mapping within this region (1:25, Santa Cruz). Glut3 immunoreactivity was revealed with the donkey anti-goat IgG-Texas Red, Santa Cruz). Quantitative analysis was carried out by flow cytometry. Briefly, at the end of each treatment, neurons were harvested, washed once with PBS and pelleted. The cell pellet was fixed by incubation with 200 μl of 2% formaldehyde for 1h at RT. Fixed cells were blocked with 4% BSA, and stained by 2 h incubation at RT with the exofacial Glut3 antibody. Stained cells were then washed twice, and finally revealed by 1 h incubation with the secondary Texas Red-conjugated antibody. Immunostained samples were checked by cytofluorimetric analysis with a CyFlow® ML flow cytometer system (Partec). Neurons were excited by an air-cooled argon 488nm laser and Texas Red signal was read on FL3 detector. The data acquired (20,000 cells per sample) were compensated, gated and analysed using FlowMax software (Partec). Each experimental condition was repeated in triplicate.

Western Blotting Analysis

Western blotting analysis for phospho-eIF-4E binding protein (p4EBP1) or phospho-IGF-IR was performed on total protein extracts (50µg) from differentiated L6 cells treated with IGF-1 (2 ng/ml), mAb₁₋₄₂ (100nM), or KLVFF (100nM) for 15 min. Samples were loaded onto 4-12% bis-Tris Glycine gel (NuPAGE, Invitrogen). After separation, proteins were transferred onto a nitrocellulose membrane (Hybond ECL, Amersham Italia) using a transblot semi-dry transfer cell. Membranes were blotted at 4°C o.n. with the following primary antibodies: rabbit anti-p4EBP1 (1:1000, Cell Signaling), rabbit-anti(Y1161)IGF-IR (1:700, Abcam), and mouse anti-β-actin (1:1000, Sigma Aldrich). Secondary goat anti-rabbit labeled with IR dye 680 (1:14.000 Li-COR Biosciences) and goat anti-mouse labeled with IRdye 800 (1:12.000 Li-COR Biosciences) were used at RT for 45 min. Hybridization signals were detected with the Odyssey Infrared Imaging System (LI-COR Biosciences).

For the analysis of phospho-IRs, cell lysates were obtained from pure neuronal cultures following a 15 min stimulation. Cell lysates (150 µg) were incubated for 2 h at 4°C on a rotating device with 20µl of the agarose conjugated anti-Insulin Receptor β (500 µg/0.25 ml agarose, Santa Cruz Biotechnology). Immunoprecipitates were pelleted, washed and resuspended in 25µl of 1x electrophoresis sample buffer containing dithiothreitol. Following SDS-PAGE and transfer, blots were probed with a monoclonal anti-phosphotyrosine antibody (1:1000, 4G10 from Merck Millipore). To search for specific hybridization signals, membranes were incubated with a horseradish peroxidase-conjugated secondary antibody, followed by the SuperSignal chemiluminescent detection system. After probing with the anti-phosphotyrosine antibody, blots were stripped for 15 min with Strip Ablot (EuroClone), and re-probed with anti-Insulin Receptor β (1:1000, Cell Signaling) to control for loading.

Western blotting analysis of phospho-IGF-IR in cultured neurons was performed on 40 µg of total proteins. Membranes were incubated over night at 4°C with the following primary

antibodies: rabbit anti-p(Y1161)IGF-IR (1:700, Abcam), and mouse anti- β -actin (1:1000, Sigma Aldrich). For the detection of hybridization signals, membranes were incubated with secondary goat anti-rabbit labeled with IR dye 680 (1:14,000 Li-COR Biosciences) and goat anti-mouse labeled with IRdye 800 (1:12,000 Li-COR Biosciences) for 45 min at RT. Signals were detected with the Odyssey Infrared Imaging System (LI-COR Biosciences). Alternatively, immunoprecipitation was carried out on neuronal lysates (150 μ g) by using the rabbit anti-IGF-IR β (10 μ g/mg protein lysate, Cell Signaling Technology).

Quantitative determination of $A\beta_{1-42}$ in Neuronal Culture Supernatants

To mimic the experimental conditions under which 6-NBDG was observed, neuronal cultures were rinsed in glucose-free HCSS and maintained for 30 min under glucose deprivation. KCl (40 mM) was added 15 min before ending the experiment. When required, γ -sec-Inhibitor IX (100 nM) was added 2 h before glucose deprivation. $A\beta_{1-42}$ was quantitated in the collected HCSS by using the Wako human/rat $A\beta_{42}$ ELISA kit, high-sensitive. This kit detects human/rat $A\beta_{x-42}$ in the 0.1-20 pmol/L range, with a sensitivity of 0.024 pmol/L; 100 μ l of undiluted cell supernatants from equivalent cultures were used for the assay.

Assessment of Insulin Release in Pancreatic INS-1E cells

Rat INS-1E β -cells were maintained in RPMI-1640 medium with 11.1 mmol/l D-glucose, supplemented with 10% FBS, 100U/ml penicillin, 100 μ g/ml streptomycin, 10 nmol/l HEPES, 2nmol/l L-glutamine, 1nmol/l sodium pyruvate and 50 μ mol/l β -mercaptoethanol. Cells were grown in T-75 flask at 37°C and 5% CO₂ and passaged every 5 days by using 0.05% trypsin-EDTA. For the experiments, cells were plated onto 24-well plates at a density of 0.5×10^6 cells/well and grown to 100% confluence. 18 h Before the experiment, growing medium was replaced with fresh medium containing 5mmol/l glucose. Insulin secretion assay was performed in HEPES balanced salt solution (HBSS) (114 mmol/l NaCl, 4.7 mmol/l KCl, 1.2 mmol/l

KH₂PO₄, 1.16 mmol/l MgSO₄, 20mmol/l HEPES, 2.5 mmol/l CaCl₂, 25.5 mmol/l NaHCO₃, 0.2% bovine serum albumin), pH 7.2. Cells were washed and maintained in 3 mM glucose HBSS for 2 h before the switch in 15 mM glucose either in the absence or in the presence of mAβ₁₋₄₂ (100nM) and KLVFF (100nM). When required, PPP (500 nM) was added 15 min before the switch. The supernatant was collected 15 min after switching, and the total insulin content was determined by the use of rat/mouse Insulin Enzyme Linked Immunosorbent Assay (ELISA) kit (Millipore).

Intra-Peritoneal Glucose Tolerance Test (GTT)

CD1 male mice (33-35 g body weight), C57BL/6J male mice (8 weeks of age), and transgenic B6.129S7-Apptm1Dbo/J male mice (APP-null, 8 weeks of age) were housed up to five for cage and fasted for 16 h prior to the test. For the GTT, a solution of glucose (20% in 0.9% NaCl) was administered by intra-peritoneal (i.p.) injection (100 µl/10 g body weight) and blood glucose was measured at different time points during the following 4h. Blood glucose was obtained from the paw and measured by using the blood glucose meter One Touch Vita, J&J. Assuming a plasma volume of 1.5 ml/mouse, stock solution of Aβ₁₋₄₂ monomers, Ac-KLVFF-NH₂ monomers or recombinant rat IGF-1 were prepared freshly in saline so to reach the plasma concentrations of 100 nM for monomers, and 2 ng/ml for IGF-1. After basal blood glucose measurements, where appropriate, monomers and IGF-1 were i.p. injected 5 min before or 15 min after glucose loading. Animal care and experimentation was in accordance with institutional guidelines.

Ex-vivo Brain Stimulation

Heterozygous TgCRND8 male mice on a 129/SVE genetic background were initially obtained from the Centre for Research in Neurodegenerative Diseases, University of Toronto, Ontario, Canada. The colony has been established in the Animal House of the University of Catania, Italy. Animal care and experimentation was in accordance with institutional guidelines. Female TgCRND8 and non-Tg littermate mice at 12 months or 8

weeks of age were used for the experiment. Mice were sacrificed by CO₂ asphyxiation, brains were removed and forebrains were sliced with a McIlwain tissue chopper. Slices were washed three times (for a total time of 30 minutes) with oxygenated Krebs-Ringer (K-R) solution (118 mM NaCl, 25 mM Hepes, 4.8 mM KCl, 1.3 mM CaCl₂, 1.2 mM KH₂PO₄, 1.2 mM MgSO₄; 25 mM NaHCO₃; 10 mM glucose), and 300 µl of the slice suspension was diluted in single tubes in a total K-R volume of 700 µl. Incubation was carried out at 37°C for 1 hour in an aerated (95% O₂, 5% CO₂) water bath. Stimulation was performed with either 1nM IGF-1 or 100 nM Aβ₁₋₄₂ monomers and terminated by adding 2 ml of ice-cold K-R. Slices were collected by centrifugation, lysed and processed for immunoprecipitation as described elsewhere. Protein concentration of the lysates was determined by the Bradford method before immunoprecipitation. Glucose consumption was assessed at the beginning and at the end of the stimulation and calculated as glucose consumption/mg of protein.

Statistics

Data were tabulated and analyzed using SigmaPlot 12.5 statistical software. Data were analyzed for determining normal distribution with Shapiro-Wilk test. Mean comparison was performed with one-way Anova or unpaired Student's t-test. Statistical significance level was always set to $p < 0.05$.

Study Approval

For animal studies, all procedures were approved by the IACUC of the University of Catania. The use of patients' clinical data and CSF samples was approved by the Ethics Committee of Azienda Ospedaliera Universitaria (AOU) Careggi of Florence.

Results

Aβ₁₋₄₂ Monomers Interact with, and Activate, type-I IGF Receptors (IGF-IRs)

We previously showed that monomeric human Aβ₁₋₄₂ protects cultured cortical neurons against excitotoxic death and death by

trophic deprivation. Neuroprotection was abrogated by inhibitors of insulin/IGF receptor signalling [13]. Here, we found that neuroprotection was also produced by rat/mouse A β ₁₋₄₂ (Figure 1, A and B), which is resistant to oligomerization [14]. It was reasonable to hypothesize that the specific amino acid sequence engaged in the aggregation process could be required for neuroprotection. The 16-20 amino acid sequence of A β ₁₋₄₂ (KLVFF) is critically involved in A β ₁₋₄₂ oligomerization and is used as template for the design of beta-sheet breakers [15]. Synthetic Ac-KLVFF-NH₂ maintained into a monomeric form (Supplemental Figure 1 A) shared the protective activity of monomeric A β ₁₋₄₂, and its action was prevented by the insulin/IGF receptor inhibitor, AG1024, or by the selective type-I IGF receptor (IGF-IR) inhibitor, PPP (Figure 1, A and B). Neither the D-isomer, klvff (Supplemental Figure 1 B), nor the scrambled peptide, VFLKF (Supplemental Figure 1 D), induced neuroprotection. In contrast, the retroinverse ffvlk peptide (Supplemental Figure 1 C), which maintains the overall spatial topology of KLVFF, was protective, albeit to a lesser extent. The human A β ₁₋₁₆ and the A β ₁₇₋₄₂ fragments were also tested. Monomers of A β ₁₋₁₆, a fragment that is produced by combined α - and β - secretase activities [16], were inactive (Figure 1, A and B). The α secretase-generated A β ₁₇₋₄₂, which is found in diffuse amyloid deposits and dystrophic neuritis associated with AD plaques [17], could not be maintained in the monomeric conformation and rapidly precipitated into large aggregates (Figure 2 E). This was consistent with previous evidence showing that N-terminal deletions enhance peptide aggregation with respect to full-length A β ₁₋₄₂ [18].

Figure 1: A β ₁₋₄₂ monomers activated IGF-IRs, but not IRs in primary neurons and recombinant cells.

The selective inhibitor of the IR superfamily, AG1024, and the preferential IGF-IR inhibitor, PPP, prevented the neuroprotective activity of A β ₁₋₄₂ monomers, either human (mAb) or rat/mouse (R/M mAb), and of Ac-KLVFF-NH₂ monomers (KLVFF) against NMDA-induced toxicity (A) or insulin-deprivation (B). In (A) and (B) values are means $\pm$ S.E.M. of eight determinations from two independent experiments. Significantly different from NMDA (*) or from the respective peptide condition (#) at $p < 0.05$ (one-way ANOVA + Fisher's LSD test). (C) Representative western blot analysis of immunoprecipitated IR beta subunit (IR) in neuronal extracts from control

cultures (CTRL) or cultures exposed for 15 min to 100 nM of either monomeric A β ₁₋₄₂ (mAB) or monomeric KLVFF peptide. IR bands are shown as control for loading. (D) Representative western blot analysis of IGF-IR p(Y1161) with the corresponding β -actin. Data refer to neuronal extracts from control cultures (CTRL), or cultures exposed for 15 min to 100 nM of either monomeric A β ₁₋₄₂ (mAB) or monomeric Ac-KLVFF-NH₂ peptide (KLVFF) both in the presence and absence of AG1024 (100 nM). Identical results were obtained in experiments in which IGF-IR p(Y1161) was assessed in IGF-IR immunoprecipitates. (E) Densitometry of three separate western blots in which IGF-IR p(Y1161) signals were normalized either on β -actin or total IGF-IR. Values (means $\pm$ S.E.M., n = 2-3) are expressed as % of the respective controls. *p < 0.05 vs. CTRL by one-way Anova + Fisher's LSD test. (F) Autophosphorylation of immunocaptured human IGF-IR in response to IGF1, mAB, or a combination of both. (G) Autophosphorylation of immunocaptured human IGF-IR in response to IGF1, KLVFF, or a combination of both. The lack of effects of the scrambled peptide, Ac-VFLKF-NH₂ (VFLKF), is also shown. Both in (F) and (G) data are the means + S.E.M. of three independent experiments and are expressed as % over basal receptor phosphorylation. *Significant at p < 0.05 vs. IGF-1 alone, or vs. basal (#) (one-way Anova + Fisher's LSD test). (H) Autophosphorylation of immunocaptured human IR-A in response to insulin (Ins), A β ₁₋₄₂ monomers (mAB) or a combination of both. Data are representative of two experiments and are expressed as % over basal receptor phosphorylation. Phosphorylation was quantitated by ELISA as described under Methods.

Based on neuroprotection data, we hypothesized that monomeric human A β ₁₋₄₂ could interact with insulin/IGF receptors *via* the 16-20 KLVFF sequence. Consistent with previous evidence [19], a basal tyrosine-phosphorylation of the immunoprecipitated insulin receptor (IR) β subunit, which reflects the activated receptor, was virtually undetectable in cultured cortical neurons both in the absence and presence of either monomeric human A β ₁₋₄₂ or Ac-KLVFF-NH₂ monomers (Figure 1 C). Because of the lack of detectable IR β phosphorylation, we could use an antibody directed against a phosphorylated tyrosine residue common to IGF-IR β and IR β (anti-p(Y1161) IGF-IR/p(Y1185) IR) to assess IGF-IR β phosphorylation without the need of immunoprecipitation. Both A β and KLVFF monomers increased IGF-IR p(Y1161) levels. This increase was no longer visible in the presence of the receptor antagonist, AG1024 (Figure 1 D, E). We searched for a direct peptide-receptor interaction using 3T3-like mouse fibroblasts with a disrupted IGF-IR gene and transfected with either human IGF-IR (R⁺ cells) or type-A IR (IR-A) (R⁻IR-A cells) cDNA [12]. On immunoadsorbed IGF-IRs derived from R⁺ cells, monomers of A β ₁₋₄₂ or Ac-KLVFF-NH₂

potentiated the ability of IGF-1 to promote autophosphorylation of the receptor-kinase domain (Figure 1 F, G), with A β ₁₋₄₂ also stimulating IGF-IR autophosphorylation in the absence of IGF-1 (Figure 1 F). In contrast, A β ₁₋₄₂ monomers had no effect on immunoadsorbed IR-A, both in the absence and presence of insulin (Figure 1 H).

A β ₁₋₄₂ Monomers Stimulate Glucose Uptake in Neurons by Activating IGF-IRs

IGF-1 is known to stimulate glucose uptake in neurons by mechanism(s) similar to those used by insulin in the periphery, including membrane translocation of glucose transporters (GLUTs) [20]. We deprived cultured neurons from glucose for 75 minutes prior to incubations with the fluorescent non-hydrolyzable glucose analogue, 6-(N-(7-nitrobenzen-2-oxa-1,3-diazol-4-yl)amino)-6-deoxyglucose (6-NBDG). During starvation, neurons were exposed for 30 min to recombinant rat IGF-1 at concentrations (5 ng/ml) that selectively activate IGF-IR and are in the physiological range of concentrations in the CSF [21]. This treatment caused a significant increase in 6-NBDG uptake, as assessed by confocal microscopy or flow-cytometry (Figure 2, B and E). Flow-cytometry showed a single cell population (Figure 2 D) from which 6-NBDG⁺ neurons were scored. Consistent with its ability to engage IGF-IRs, monomeric A β ₁₋₄₂ (100 nM) increased the population of 6-NBDG⁺ neurons following starvation, and its action was prevented by the IGF-IR inhibitor, PPP (Figure 2, C and E). Thus, A β ₁₋₄₂ monomers displayed IGF-1-like metabolic activity in cultured neurons. This, combined with the evidence that A β ₁₋₄₂ is released from neurons in response to synaptic activity [22], provided the hint for testing the hypothesis that A β ₁₋₄₂ monomers might function to increase glucose uptake during neuronal activation. A depolarization pulse with KCl (40 mM for 15 minutes) caused a significant increase in glucose uptake, which occluded any additional effect of A β ₁₋₄₂ monomers (Figure 2 F). Depolarization-induced glucose uptake was prevented by pretreatment with PPP (500 nM for 20 minutes), suggesting that endogenous activation of IGF-IRs was required for activity-dependent energy supply (Figure 2 F). Addition of a γ -secretase

inhibitor (γ -secretase inhibitor IX, 100 nM), which blocked the endogenous production of $A\beta_{1-42}$ (Figure 2 G), blunted depolarization-induced glucose uptake, which was re-established by exogenous $A\beta_{1-42}$ monomers (Figure 2 F). In neuronal cultures prepared from APP-null mice, KCl-induced depolarization failed to enhance glucose uptake unless exogenous $A\beta_{1-42}$ was added (Figure 2 H).

Figure 2: $A\beta_{1-42}$ monomers stimulated glucose uptake in neurons by activating IGF-IRs.

Confocal images of 6-NBDG uptake in live neurons exposed to either IGF-1 (5ng/ml) (B) or monomeric $A\beta_{1-42}$ (mAb) (C) for 30 min after starvation, scale bar = 10 μ m. (D) Representative scatter plot of the neuronal population examined by flow-cytometry. Percentage of 6-NBDG⁺ neurons following treatments was scored by flow cytometry in (E) and (F). (E) The IGF-IR antagonist, PPP, prevented neuronal 6-NBDG uptake induced by $A\beta_{1-42}$ monomers (mAb). Values are means $\pm$ S.E.M. of two independent experiments.

*Significant at $p < 0.05$ vs. controls (CTRL), or vs. mAb (#) (one-way Anova + Fisher's LSD test). (F) The IGF-IR antagonist, PPP, and the γ -secretase inhibitor IX (γ -Sec inh) prevented neuronal 6-NBDG uptake induced by a 15 min depolarization pulse with KCl. Values are means $\pm$ S.E.M. of two independent experiments. *Significant at $p < 0.05$ vs. controls (CTRL), or vs. KCl (**), or vs. γ -Sec inh + KCl (#) (one-way Anova + Fisher's LSD test). (G) γ -Secretase inhibitor IX blocked the endogenous production of $A\beta_{1-42}$ under both basal and depolarizing conditions. Values are means $\pm$ S.E.M. of three determinations from one representative experiment that was carried out under conditions similar to those utilized for the assessment of neuronal 6-NBDG uptake. γ -Secretase inhibitor IX (γ -Sec Inh) was present in the cultures for 2 h before washing and shifting into a glucose-free buffer for 30 min. Glucose-free buffer collected after 30 min, in the absence of γ -sec inh., is reported as control condition. Where indicated, KCl was added 15 min before collecting the buffer. $A\beta_{1-42}$ was quantitated in the collected buffer by using the Wako human/rat $A\beta_{42}$ ELISA kit, high-sensitive. Significant at * $p < 0.05$ and at ** $p < 0.01$ vs. control, and at # $p < 0.01$ vs. KCl alone (one-way ANOVA + Fisher's LSD test). (H) Percentage of 6-NBDG⁺ neurons in APP-null cultures and related wt cultures. Values are means $\pm$ S.E.M. *Significant at $p < 0.05$ vs. respective controls (CTRL) in the wt ($n = 3-4$) and in the APP-null condition ($n = 6-9$) (one-way Anova + Holm-Sidak test).

To examine whether native human $A\beta$ could share this activity, we carried out a set of experiments using CSF samples obtained from 4 MCI and 4 AD patients (Figure 3 A). CSF levels of $A\beta_{1-42}$ in MCI patients (1032 ± 102 pg/ml) approximated the reference values of healthy individuals, whereas average levels in AD patients were about 3 fold lower (384 ± 36 pg/ml). CSF glucose contents varied among samples (Figure 3 A), and were made uniform by addition of exogenous glucose. Cultured neurons, incubated with inhibitor IX to block the endogenous production of $A\beta_{1-42}$, were starved for 45 minutes and then incubated with human CSF. Glucose uptake stimulated by high K^+ did not significantly differ between cultures incubated with MCI and AD CSF, although a trend to a reduction in AD-CSF treated cultures was seen (Figure 3 B). We used the neutralizing 4G8 monoclonal antibody, which bound $A\beta$ but not APP in human CSF samples under non-denaturing conditions. Native CSF samples, as immunoprecipitated by 4G8 antibody and revealed by the G2-13 antibody, showed the 4 kD $A\beta_{1-42}$ monomer, but not the expected 100 kD band corresponding to APP (Figure 3 C). Addition of the 4G8 antibody (100 ng/ 50 μ l CSF) significantly reduced glucose uptake at least in cultures treated with MCI CSF (Figure 3 B and related legend). This indicated

that native human A β was able to support glucose uptake in neurons.

Figure 3: Native human A β stimulated glucose uptake in neurons. (A) Summary of the cases used in this study. CSF samples were from the Department of Neurological and Psychiatric Sciences, University of Florence. Clinical diagnosis of AD was defined according to the Diagnostic and Statistical Manual of Mental Disorders criteria (DSM-IV). Clinical diagnosis of MCI was defined according to Petersen's validated criteria (Petersen et al., 2001). CSF A β ₁₋₄₂ was quantitated by INNOTEST β -amyloid (1-42) from Innogenetics. (B) Contribution of CSF A β monomers to depolarization-induced neuronal glucose uptake both in the absence (IgG2b isotype control) and in the presence (4G8) of a neutralizing anti-A β antibody. Neurons were pre-exposed to the γ -secretase inhibitor IX and underwent a 15 min depolarization pulse with 400 mM KCl (γ -Sec Inh + KCl). Mean values of glucose uptake (mg/dl) after the pulse were the following: 47.75 ± 4.77 vs. $33.87 \pm 4.54^*$ (*different at $p < 0.05$, $n = 4$) in the MCI condition in the presence of IgG2b or 4G8, respectively; 38.13 ± 6.03 vs. 27.72 ± 2.14 ($n = 4$) in the AD condition in the presence of IgG2b or 4G8, respectively. Each n was run in duplicate and expressed as mean. (C) The β -amyloid (17-24) 4G8 monoclonal antibody does not bind APP in human CSF samples under non-denaturing conditions. 200 μ l of a MCI CSF sample, containing 1076 pg/ μ l of A β ₁₋₄₂, were treated with 4G8 antibody (Covance, 100 ng/50 μ l) under native conditions for 2 h, before proceeding with the immunoprecipitation protocol. Western blot analysis was then performed both in the immunoprecipitated pellet (left) and in the

supernatant (right). Three different antibodies were used to reveal APP and/or A β in the samples. Both the 6E10 monoclonal antibody (Covance, 1:1000 dilution) and the 12B2 monoclonal antibody (IBL International, 5 mg/ml) failed to reveal the expected 100 kD band corresponding to APP in the pellet (left), but showed the APP band in the supernatant (right) (see arrow). Bands smaller than 100 kD, likely corresponding to A β aggregates, were visible both in the supernatant and in the immunoprecipitated. An additional antibody, the G2-13 monoclonal antibody that specifically recognizes A β 1–42 at the C-terminus (Millipore, 1 mg/ml), was sensitive enough to detect the 4 kD A β 1–42 monomer at the electrophoresis front of the immunoprecipitated (left) (see arrow).

A β ₁₋₄₂ Monomers Promote Membrane Translocation of Glut3 in Neurons by Activating IGF-IRs

The membrane transporters, Glut3 and Glut4, mediate glucose transport in neurons [23]. Glut3 has a neuropil localization [23], which might enable glucose transport in neurons to uphold glucose uptake during synaptic activity. Depolarization is known to promote the fusion of Glut3 vesicles with the cell surface in neurons [24]. In our cultures, K⁺-induced depolarization increased Glut3 immunoreactivity in neuronal threads, as well as in perikarya and axon hillocks (Figure 4, G and H). A β ₁₋₄₂ monomers induced a similar pattern of Glut3 immunoreactivity (Figure 4, C and D), which was prevented by pretreatment with PPP (Figure 4, E and F). The intense Glut3 immunoreactivity profiling neuronal perikaryon was paralleled by a reduction of Glut3 signal spread assayed in a z-stack series of neuronal slices (Figure 5 I), suggesting that A β ₁₋₄₂ monomers were promoting Glut3 translocation. Glut3 translocation was also assessed by immunolabeling neurons with an antibody raised against the exofacial epitope of Glut3 in the absence of membrane permeabilization. Both monomeric A β ₁₋₄₂ and Ac-KLVFF-NH₂ increased immunoreactivity for exofacial Glut3 as assessed by immunocytochemistry and cytofluorimetric analysis (Figure 4, L-R). Consistent with the membrane translocation of Glut3, A β ₁₋₄₂-induced glucose uptake occurred at concentrations (1.5 mM) at which only Glut3, which has the lowest K_m among all Gluts, is likely to function [25] [extracellular glucose (mg/dl): 32.3 $\pm$ 4.7 and 18.7 $\pm$ 2 - control vs. 100 nM A β ₁₋₄₂, respectively; n = 4-5, p = 0,0127]. This putative Glut3-dependent glucose uptake was sensitive to the PI-3K-inhibitor, LY294002, [extracellular

glucose (mg/dl): control (30.810 ± 1.975), 100 nM $A\beta_{1-42}$ (17.90 ± 0.473)*, 100 nM $A\beta_{1-42} + 10 \mu\text{M}$ LY294002 (26.950 ± 3.086)*; $n = 4$, * $p = 0.004$ compared to the respective controls by one-way Anova + Fishers' LSD], consistent with our previous demonstration that $A\beta_{1-42}$ monomers activate the PI-3K/AKT pathway in neurons [13].

Figure 4: Monomers of $A\beta_{1-42}$ and Ac-KLVFF-NH₂ induced Glut3 translocation at neuronal plasma membranes.

Confocal images of neurons co-immunolabeled for Glut3 and β -actin following 10 min stimulation with 100 nM $A\beta_{1-42}$ monomers (mAB) both in the absence (C, D) and presence of the IGF-IR antagonist, PPP (E, F), or with 40 mM KCl (G, H). Before stimulations, neurons were glucose-deprived for 30 min. Arrows point to Glut3 immunoreactivity profiling neuronal perikarya in (C), (D) and (G); arrowheads point to Glut3 immunoreactivity profiling neuronal threads in (D) and (H). Scale bars indicate low magnification (A, C, E, G) and high magnification (B, D, F, H) images. (I) Glut3 signal spread assayed in a z-stack series of neuronal slices as described under methods. Ten random fields for each experimental condition were imaged, and ten neurons/field were scored.

Each treatment was repeated twice in three separate experiments. Bars represent fold decrease of signal spread compared to controls (CTRL). *Significant at $p < 0.05$ vs. controls (CTRL), or vs. mAb (#) (one-way Anova + Fisher's LSD test). (L, N, P) Confocal imaging of the N-terminal extracellular domain of Glut3 in adherent non-permeabilized neurons. Immunostaining was barely visible under control conditions (CTRL). Arrowheads point to plasma membrane profiles in neurons that were exposed to 100 nM of either monomeric A β_{1-42} (mAb) (N) or Ac-KLVFF-NH $_2$ monomers (KLVFF) (P) for 10 min after glucose starvation. Scale bar = 10 μ m. (M, O, Q, R) Glut3 immunostaining carried-out in harvested non-permeabilized neurons and quantified by flow cytometry. Representative histograms displaying Glut3 fluorescence intensity (FL3) on the x-axis and the number of events (counts) on the y-axis are shown for controls (M), mAb (O) and KLVFF (Q). The percentage of positive neurons is gated under RN1. (g) Bars represent means $\pm$ S.E.M of three determinations. 20,000 Neurons/determination were acquired. *Significant at $p < 0.05$ vs. controls (CTRL) (one-way Anova + Fisher's LSD test).

Difference in IGF-IR Response to A β_{1-42} Monomers between AD Transgenic Mice and Wild-Type Littermates

We examined responses to IGF-1 and A β_{1-42} monomers in forebrain slices prepared from AD mutant mice and their wt littermates. We used both 12-month old CRND8 mice, which show severe A β plaque burden [26], and 8-week old CRND8 mice, which show sporadic A β deposits and perform normally [27]. At 12 months of age, physiological concentrations of exogenous IGF-1 (1 nM) enhanced Tyr-phosphorylation of IGF-IRs in wt but not in CRND8 slices. In contrast, exogenous monomeric A β_{1-42} (100 nM) enhanced IGF-IR phosphorylation in CRND8 but not in wt slices. Basal glucose consumption was lower in CRND8 slices and unresponsive to IGF-1. In contrast, monomeric A β_{1-42} substantially increased glucose consumption in CRND8 slices. None of the treatments influenced glucose consumption in wt slices (Table 1). At 8 weeks of age, the IGF-IR response to either IGF-1 or A β_{1-42} monomers was similar in forebrain slices of CRND8 mice and wt mice, as it was basal glucose consumption (Table 1).

Table 1: Difference in the forebrain response to either IGF1 or A β ₁₋₄₂ monomers between CRND8 transgenic and non-transgenic littermate mice.

	TgCRND8 (1 year old)		Non-Tg (1 year old)	
	p(Y1161) IGF-IR levels (% of basal)	glucose consumption (μ mol)/hr	p(Y1161) IGF-IR levels (% of basal)	glucose consumption (μ mol)/hr
Basal	100	0.2 $\pm$ 0.02	100	0.35 $\pm$ 0.01
IGF1, 1 nM	88.5 $\pm$ 5.35	0.2 $\pm$ 0.018	153.467 $\pm$ 14.91*	0.35 $\pm$ 0.02
mA β , 100 nM	147.767 $\pm$ 4.68*	0.34 $\pm$ 0.014 [#]	74.543 $\pm$ 12.25	0.35 $\pm$ 0.015

Peripheral IGF-1-like Actions of A β ₁₋₄₂ Monomers

To strengthen the evidence that monomeric A β ₁₋₄₂ has IGF-1-like activity, we extended the analysis to classical peripheral actions of IGF-1. L6 rat skeletal muscle cells express both IGF-IRs [28] and Glut3 [29]. We assessed the phosphorylation state of the IGF-IR β subunit by using the antibody directed against the specific phosphorylated tyrosine residue, Y1161, common to the IR β subunit. Because the density IGF-I binding sites is one-hundred fold higher than the density of insulin binding sites in L6 cells [28], we used the anti-pY1161 antibody for the assessment of IGF-IR β phosphorylation without immunoprecipitation. In L6 myotubes, IGF-1 stimulated IGF-IR phosphorylation at concentrations as low as 2 ng/ml (Figure 5 A). Both monomeric A β ₁₋₄₂ and Ac-KLVFF-NH₂ behaved similarly to IGF-I (Figure 5 A), and enhanced the amount of phosphorylated high-molecular weight eIF-4E binding protein, 4E-BP1 (Figure 5 A), which is a downstream target of both the MEK/ERK and the PI-3K/AKT pathways [30]. Similar to IGF-1, A β ₁₋₄₂ monomers also increased Glut3 immunoreactivity in myotubes (Figure 5 B). Monomeric A β ₁₋₄₂ and Ac-KLVFF-NH₂ (both at a 100 nM) stimulated 6-NBDG uptake as assessed by confocal microscopy (Figure 5, C and D) and cytofluorimetric analysis (Figure 6 E). Under all treatments, 6-NBDG uptake was prevented by the MEK inhibitor, UO126, but not by the PI-3K inhibitor, LY294002 (Figure 5 E).

Physiological concentrations of IGF-1 inhibit insulin secretion from pancreatic β cells [31]. Similarly to IGF-1, monomers of A β ₁₋₄₂ and Ac-KLVFF-NH₂ (injected i.p. to obtain plasma concentrations of 100 nM) caused a transient increase in blood glucose levels in CD1 mice undergoing a glucose tolerance test (GTT), which reflects the inhibition of insulin secretion (Figure 6 A). Blood glucose levels during GTT were higher in the C57BL/6J strain than in the CD1 strain, consistent with the evidence that C57BL/6J mice have an inherited impaired glucose tolerance [32]. In C57BL/6J mice, monomers of Ac-KLVFF-NH₂ did not affect significantly blood glucose levels during GTT; however, in the congenic APP-null mice undergoing GTT, monomers of Ac-KLVFF-NH₂ were able to sustain the rise in

blood glucose levels when injected 15 min after glucose load (Figure 6 B).

Figure 5: IGF-1-like actions of $A\beta_{1-42}$ monomers in L6 rat skeletal myotubes. (A) Left side: representative western blot of p(Y1161) IGF-IR in L6 extracts from control cultures (CTRL), or cultures exposed for 15 min to 100 nM of either monomeric $A\beta_{1-42}$ (mAB) or monomeric Ac-KLVFF-NH₂ peptide (KLVFF). β -actin bands are shown as control for loading. Bars refer to densitometric analysis of three separate western blots. Values (means $\pm$ S.E.M., n = 3) are expressed as % of the respective controls. *p < 0.05 vs. CTRL by one-way Anova + Fisher's LSD test. Right side: representative western blot analysis of phosphorylated 4E-BP1 (p4E-BP1) in L6 extracts from control cultures (CTRL) or cultures exposed for 15 min to 100 nM of either monomeric $A\beta_{1-42}$ (mAB) or monomeric Ac-KLVFF-NH₂ peptide (KLVFF). Levels of high-molecular weight p4E-BP1 isoform (see arrow) were increased by either mAB or KLVFF. β -actin bands are shown as control for loading. IGF-1 (2 g/ml) was used as a positive control within the experiments. Bars refer to densitometric analysis of three separate western blots. Values (means $\pm$ S.E.M., n = 3-4) are expressed as % of the respective controls. *p < 0.05 vs. CTRL by one-way Anova + Fisher's LSD test. (B) $A\beta_{1-42}$ monomers increased Glut3

immunoreactivity in L6 cells. Confocal images of L6 myotubes co-immunolabeled for Glut3 and β -actin following 15 min stimulation with 100 nM $A\beta_{1-42}$ monomers (mA β) or 2ng/ml IGF-1 are shown; scale bar = 140 μ m. (C, D, E) $A\beta_{1-42}$ monomers promoted glucose uptake in L6 rat skeletal myotubes. Confocal images of 6-NBDG uptake in live L6 cells exposed to either monomeric $A\beta_{1-42}$ (mA β) or IGF-1 (2ng/ml) for 15 min after starvation are shown in (C); scale bar = 510 μ m. In (D), 6-NBDG fluorescence intensity was quantified by confocal imaging and represented as fold change with respect to basal. Fluorescence intensity was calculated from 300 cells/experiments in two independent experiments. *Significant at $p < 0.05$ vs. basal, or vs. the respective control condition (#) (One-Way Anova + Fisher's LSD test). In (E) the mean 6-NBDG fluorescence intensity of the cell population was quantified by cytofluorimetric analysis. Bars represent means + S.E.M of three-four determinations. 10,000 cells/determination were acquired. #Significant at $p < 0.05$ vs. the respective control condition (one-way Anova + Fisher's LSD test). UO126 and LY294002 were applied during starvation and throughout the course of the experiment.

We also used INS-1E insulinoma cells, which secrete insulin in response to glucose [33]. We observed a 1.2 - 2 fold increase in insulin release by shifting the cells from low (3 mM) to high (15 mM) glucose concentrations. Monomers of $A\beta_{1-42}$ and Ac-KLVFF-NH₂ inhibited glucose-stimulated insulin secretion, and the effect was prevented by PPP (Figure 6 C). Thus, monomeric $A\beta_{1-42}$ and its functional epitope, KLVFF, exhibited IGF-1-like effects also outside the CNS.

Figure 6: Peripheral effects of $A\beta_{1-42}$ monomers. (A) $A\beta_{1-42}$ monomers transiently increased blood glucose levels in CD1 male mice undergoing a glucose tolerance test (GTT). This effect was mimicked by the Ac-KLVFF-NH₂ peptide and by IGF-1. Fasted mice were i.p. injected with either $A\beta_{1-42}$ monomers (mAb), KLVFF monomers or IGF-1 five minutes

before glucose loading (2g/kg). Plots represent the fold increase of glucose levels over basal in 4 animals per experimental condition. *Significantly different from control (CTRL) at $p < 0.05$ (One-Way Anova + Fisher's LSD test). Data are from one experiment repeated three times with similar results. (B) Ac-KLVFF-NH₂ monomers sustained the rise in blood glucose levels in APP-null mice undergoing GTT. Mice, either C57BL/6J (WT) or APP-null, were i.p. injected with the Ac-KLVFF-NH₂ peptide 15 min after glucose load. *Significantly different from APP-null-saline at $p < 0.001$ ($n = 4-10$ animals/group, One-Way Anova + Fisher's LSD test). (C) A β_{1-42} monomers reduced glucose-stimulated insulin release in pancreatic INS-1E cells. This effect was mimicked by the Ac-KLVFF-NH₂ peptide and was prevented by the IGF-IR antagonist, PPP. Data, representative of three experiments, are fold change of glucose-stimulated insulin release. Significantly different from the 15 mM glucose condition (*), or the respective controls (#) at $p < 0.05$ and (One-Way Anova + Fisher's LSD test).

Discussion

The amyloid hypothesis postulates that A β_{1-42} , in a variety of aggregated forms, ultimately causes neurodegeneration in AD [1]. However, drugs targeting A β_{1-42} burden have been so far unsuccessful [34], suggesting the need to explore the properties of the peptide beyond the process of aggregation. We have previously shown that monomeric A β_{1-42} has a broad neuroprotective activity, which is sensitive to inhibitors of insulin/IGF-1 signaling [13]. Here we demonstrate that the KLVFF amino acid sequence of A β_{1-42} , which is recruited in the aggregation process, retained the neuroprotective properties of full-length A β_{1-42} . The additional findings that the retro-inverse pentapeptide (ffvIk) was neuroprotective, whereas the D-pentapeptide (klvff) was inactive, indicated a ligand-receptor interaction. IR and IGF-IR are homologous receptors, engaging many of the same intracellular pathways in the CNS and in the periphery [35]. We have found that both monomeric human A β_{1-42} and KLVFF selectively stimulated Tyr-phosphorylation of native IGF-IRs in primary cortical neurons. A direct activation of IGF-IRs by either monomeric A β_{1-42} or KLVFF was demonstrated on immuno-captured IGF-IRs derived from recombinant cells. Under this condition, monomers of both A β_{1-42} and KLVFF potentiated the ability of IGF-1 to promote autophosphorylation of the receptor-kinase domain, with A β_{1-42} also displaying a low intrinsic efficacy. We concluded that monomeric A β_{1-42} and KLVFF are able to interact with IGF-IRs,

acting as positive allosteric modulators, and that the KLVFF sequence of A β ₁₋₄₂ is involved in this interaction. Therefore, binding of A β ₁₋₄₂ to IGF-IR may be lost when the KLVFF sequence becomes engaged in the formation of A β ₁₋₄₂ aggregates.

There is evidence that the IGF-IR is resistant to IGF-1 activation in the AD brain [7]. Why the IGF-IR cannot be activated even by pharmacological doses of IGF-1 in AD brain is so far unexplained [7]. Our results obtained in brain tissue from CRND8 mice of different ages suggest that this could be due to the loss of A β ₁₋₄₂ monomers accompanying the course of the pathology. In forebrain slices from old CRND8 mice with a severe A β load, as opposed to slices obtained from young CRND8 brains, IGF-1 was unable to activate IGF-IRs, which, instead, remained sensitive to A β ₁₋₄₂ monomers. We suggest that, by acting as an allosteric modulator, the exogenous monomer of A β ₁₋₄₂ could be able to tune IGF-IRs in a way that cannot be accomplished by the orthosteric ligand, namely IGF-1 [36], and this effect would be unmasked under the condition of an advanced plaque burden and ensuing depletion of endogenous monomers. Whether or not the A β ₁₋₄₂ monomer can activate native IGF-IR signalling in the absence of IGF-1, thus behaving as an allosteric agonist, remains to be established. In the brain, the endogenous tone of IGF-1 is like to decline with age [2] and to rise in conjunction with pathological events [37]. The evidence that in old non-transgenic mice (i.e., in the aged-non injured brain), as opposed to young non-transgenic mice, A β ₁₋₄₂ monomers failed to activate IGF-IRs suggests that, under our conditions, endogenous IGF-1 could be required for the activity of monomeric A β ₁₋₄₂.

IGF-IRs and IRs control glucose uptake in neurons as they do in peripheral cells, i.e. by promoting membrane translocation of specific types of glucose transporters [20,23]. Glucose uptake is particularly relevant during network activation, when activated neurons do not rely on astrocyte-released lactate to meet their energy demand [38]. Neurons express Glut3, Glut4, and Glut8; among these, Glut 4 is insulin-sensitive, but it is expressed only in few neuronal populations, whereas Glut8 never associates with the plasma membrane [23]. We found that monomeric A β ₁₋

₄₂ and KLVFF were able to enhance glucose uptake in neurons *via* the activation of IGF-IRs, and this action was associated with membrane translocation of Glut3, which is localized mostly to the neuropil [23]. In agreement with the evidence that A β ₁₋₄₂ monomers activate the PI-3K/AKT pathway in neurons [13], the PI-3K-inhibitor, LY294002, prevented glucose uptake induced by monomeric A β ₁₋₄₂. More important, we demonstrated that A β ₁₋₄₂ was necessary for activity-dependent glucose uptake in neurons. In fact, a depolarizing pulse of K⁺ ions was unable to stimulate glucose uptake if endogenous production of A β ₁₋₄₂ was blunted by an inhibitor of γ -secretase or by the genetic deletion of APP. Under both circumstances, depolarization-induced glucose uptake was rescued by exogenous application of monomeric A β ₁₋₄₂, either synthetic or derived from human CSF samples. Although synthetic A β differs from natural A β in terms of effective concentrations [39], our data demonstrated that the effects of the synthetic A β monomer were reproduced by the endogenous rat peptide and by the human-derived peptide.

Monomeric A β ₁₋₄₂ and KLVFF exhibited IGF-1-like activity also in peripheral cells, including pancreatic β cells and skeletal muscle cells. In both systems, as in neurons, the endogenous tone of IGF-1 ([40,41]; see also neuronal cultures in the methods section) was likely to be relevant for the action of KLVFF, but could be dispensable for the action of A β ₁₋₄₂ monomers, which, at least in recombinant R⁺ cells, displayed a small agonist activity. In skeletal muscle cells, monomeric A β ₁₋₄₂ and KLVFF reproduced the intrinsic signalling properties of IGF-1, including the phosphorylation of the protein synthesis regulator, 4E-BP1, membrane translocation of Glut3, and MEK/ERK-dependent glucose uptake. This last finding was consistent with the evidence that, in L6 skeletal muscle cells, Glut3 depends on the MEK/ERK pathway for membrane translocation [42]. Overall, these data strengthen the evidence that A β ₁₋₄₂ monomers were acting on IGF-IRs, suggesting a possible contribution of monomers to the control of peripheral glucose homeostasis.

Accordingly, due to the ability to inhibit insulin secretion, monomers of both A β ₁₋₄₂ and KLVFF raised blood glucose levels in outbred mice injected i.p. with a glucose load. We did not

observe this effect in inbred mice with an inherited impaired insulin release [32], unless they were carrying a genetic deletion of APP. Hence, the condition of constitutive glucose intolerance could determine a desensitized response to amyloid, which was maintained instead in APP-null mice lacking endogenous amyloid. Although these data are a corollary of the main finding that monomeric $A\beta_{1-42}$ acts as a positive allosteric modulator of IGF-IRs, they point to potentially relevant glucoregulatory properties of peripheral amyloid deserving further investigation.

With regard to the central IGF-1-like metabolic actions of $A\beta_{1-42}$ monomers, our data hint at the relevance of a loss of $A\beta_{1-42}$ monomers in the pathophysiology of AD. FDG-PET studies have shown low rates of brain glucose metabolism in young adult at genetic risk of late-onset AD [8], and in presymptomatic individuals with familial AD [9]. FDG autoradiography in transgenic AD mice has demonstrated a pattern of progressively reduced metabolic activity similar to that observed in human AD [43]. The profound resistance of the AD brain to IGF-1 [7], which has been replicated in AD transgenic mice (Zhang et al., [44] and present manuscript), could account for the observed glucose metabolic deficits [6,43]. This suggestion is consistent with the evidence that glucose metabolism in most neurons is insulin insensitive [7,45] and, instead, regional glucose utilization parallels IGF-1 and IGF-IR expression at least in the developing brain [37]. We propose that the impairment of brain glucose uptake, preceding the clinical onset of AD by years, could be due to the early process of amyloid aggregation causing pauperization of $A\beta$ monomers, which normally modulate IGF-IRs. Over the years, amyloid load could progressively overcome the metabolic reserve that supports cognitive function [4] leading to the onset of dementia. Finally, the evidence that brain metabolism in AD patients is more severely impaired during activation than at rest [46] is consistent with the hypothesis that the reduced neuronal secretion of $A\beta$ occurring with aging [47,48] might impair the brain ability to cope with transient needs in neuronal energy provision.

Supplementary Material

Supplementary Figure 1: Pentapeptides (A-D) maintained a monomeric, yet flexible conformational state overtime. Circular Dichroism spectra of (A) KLFFF (square), (B) klvff (circle), (C) ffvlk (triangle up) and (D) VFLKF (triangle down) peptide solutions, incubated at 37 °C, at t = 0 min (x symbol) and t = 1200 min (+ symbol), respectively. All the CD spectra exhibited dichroic bands (either positive or negative depending on the peptide stereo-configuration) around 200 - 230 nm, suggesting that the pentapeptides did not adopt any preferred secondary structure in aqueous solution. Inset: ThT fluorescence intensities (open symbol) at 480 nm and Rayleigh scattering intensities (filled symbol) at 400 nm as a function of time for peptide samples

incubated at 37°C. Both Th-T fluorescence and Rayleigh scattering measurements confirmed the un-aggregated condition and featureless conformational state of the peptide chains. A β_{17-42} samples (E) failed to maintain the monomeric state. Freshly prepared samples were dissolved in 10 mM phosphate buffer pH=7.2 containing Th-T in a fivefold excess with respect to A β_{17-42} concentration. The high Th-T fluorescence intensity values that were observed soon after peptide dissolution indicated a rapid formation of amyloid aggregates at both 1 and 10 μ M concentrations; the rapid Th-T fluorescence decay indicated, instead, peptide precipitation into large aggregates.
